ABSTRACT: Internal gravity waves (GWs) are ubiquitous in the atmosphere, making significant 22 contributions to the mesoscale motions. Since the majority of their spectrum is unresolved in global 23 circulation models, their effects need to be parameterized. In recent decades GWs have been 24 increasingly studied in high-resolution simulations, which, unlike direct observations, allow us 25 to explore full spatio-temporal variations of the resolved wave field. In our study we analyze and 26 refine a traditional method for GW analysis in a high-resolution simulation on a regional domain 27 around the Drake Passage. We show that GW momentum drag estimates based on the Gaussian 28 high-pass filter method applied to separate GW perturbations from the background are sensitive 29 to the choice of a cutoff parameter. The impact of the cutoff parameter is higher for horizontal 30 fluxes of horizontal momentum, which indicates higher sensitivity for horizontally propagating 31 waves. Two modified methods, which choose the parameter value from spectral information, 32 are proposed. The dynamically determined cutoff is mostly higher than the traditional cutoff 33 values around 500 km, leading to larger GW fluxes and drag, and varies with time and altitude. 34 The differences between the traditional and the modified methods are especially pronounced during 35 events with significant drag contributions from horizontal momentum fluxes. 36

SIGNIFICANCE STATEMENT: In this study, we highlight that the analysis of gravity wave activity from high-resolution datasets is a complex task with a pronounced sensitivity to the methodology, and we propose modified versions of a classical statistical gravity wave detection method enhanced by the spectral information. Although no optimal methodology exists to date, we show that the modified methods improve the accuracy of the gravity wave activity estimates, especially when oblique propagation plays a role.

1. Introduction

Internal gravity waves (GWs) manifest themselves in the flow as oscillations supported by 44 the buoyancy force within the fluid (Holton 2004). One of their crucial properties is the variety 45 of temporal and spatial scales on which they emerge. Horizontal wavelengths of GWs range from 46 thousands to a few kilometres (Fritts and Alexander 2003), being increasingly affected by rotation 47 at the upper wavelength bound (e.g. inertia-GWs) and by nonhydrostatic effects with dominating 48 vertical velocity component at the lower bound. They dominate the mesoscale wave spectrum 49 (wavelengths in the order of 10 - 1000 km) in the middle atmosphere (Andrews et al. 1987), but 50 they also impact the synoptic (Achatz et al. 2017) and planetary scale circulations (Andrews et al. 51 1987) and can also directly influence the surface weather conditions including extreme weather 52 events (Damiens et al. 2018). Furthermore, they impact the mesospheric circulation and are 53 responsible for the upper mesospheric wind reversal, the cold summer mesopause and warm winter 54 stratopause (Dunkerton 1978; Lindzen 1981). 55

The fact that GWs exist and exert influence across a wide range of scales presents a challenge 56 for numerical climate atmospheric models, as a significant portion of the GW spectrum is smaller 57 than the scale of the computational grid. Hence, momentum deposition and other possible effects 58 of the unresolved part of the spectrum have to be parameterized. GW parameterization schemes rely 59 on various simplifications of the sourcing, propagation and dissipation processes and employ several 60 tunable parameters, as reviewed recently in Plougonven et al. (2020). Given the importance of GW 61 parameterizations for model circulation and dynamics (Polichtchouk et al. 2018; Van Niekerk et al. 62 2018a; Eichinger et al. 2020; Sacha et al. 2021), this brings an undesirable level of uncertainty 63 to the simulations. 64

Constraining the tunable parameters is complicated, because this requires general knowledge 65 of GW global distribution, wavelengths, frequencies, momentum fluxes, etc. (Alexander et al. 66 2010), which cannot be to date derived from global scale (satellite) observations. That said, 67 increasing attention is being paid to high-resolution numerical models that are becoming capable 68 of simulating the life-cycle of a broad spectrum GWs (Smith et al. 2007; Kruse et al. 2022). 69 For deriving momentum flux (MF) and GW drag (GWD) estimates from such complex data sets 70 (often in a bounded domain), Reynolds decomposition is usually applied and some type of a GW 71 separation method has to be used. 72

Many approaches exist to date ranging from theoretical approaches based on various forms of 73 balanced-unbalanced flow separation (Mirzaei et al. 2017; Gaßmann 2019) including potential 74 vorticity inversion techniques (Viúdez 2012), cosine (Denis et al. 2002), modal (Stephan et al. 75 2021, 2022) or Helmholtz (Bühler et al. 2014; Lindborg 2015) decomposition or the Transformed 76 Eulerian mean framework (Gupta et al. 2021) or its generalization (Kinoshita and Sato 2013), to 77 approaches invoking various forms of spectral methods and transforms (Wright and Gille 2013; 78 Preusse et al. 2014; Schoon and Zülicke 2018; Kruse and Smith 2015; Dörnbrack 2021). In our 70 study, we apply two methods that have been used in the literature before for GW separation and 80 consequent momentum flux evaluation in a limited model domain, that allow easy application and 81 straightforward GWD computation, the S3D method (Lehmann et al. 2012) and high-pass filtering 82 method of Kruse and Smith (2015). We demonstrate the sensitivity of the resulting GWD estimates 83 on the method and propose two modifications of the high-pass filtering method based on underlying 84 spectral analysis that can mitigate the uncertainty of GWD estimates connected with the subjective 85 choice of the cutoff wavelength in the filter. 86

In Section 2 of the paper, we first review the theory of the high-pass filter method for GW sepa-87 ration, the kinetic energy spectrum calculation and S3D method and we described the algorithms 88 of the modified methods. In Section 3 the analysed dataset is described together with the method-89 ology for drag estimates. In Section 4, we first show the kinetic energy spectrum of the combined 90 data (Section 4a) and the uncertainty of the standard high-pass filter method (Section 4b). The 91 resulting drag estimates from different methods are compared in Section 4c. Finally, in Section 4d, 92 the distribution of the error among the individual components of GWD is studied. The paper ends 93 with discussion and concluding remarks in Section 5. 94

95 2. Methodology

96 a. High-pass Filter Method

⁹⁷ We implement the high-pass filter method introduced in Kruse and Smith (2015) on a Cartesian ⁹⁸ domain with constant 3-km horizontal resolution. The method uses a Gaussian filter, which mod-⁹⁹ ulates simulated fields of velocity components by convolution with a Gaussian function (Gonzalez ¹⁰⁰ and Woods 2008).

In the first step, a low-pass filter is applied to the data to identify the non-mesoscale or GW part of the field. The scales of GWs to be filtered out are set by choosing a cutoff parameter L corresponding to the width of the Gaussian function in the Fourier/wavenumber space. GW perturbations are subsequently obtained as the difference between the original and low-pass filtered velocity fields.

In practice, the fast Fourier transform (FFT) algorithm is used instead of convolution. The Fourier
 coefficients are multiplied by the response function

$$\hat{r}(k,l) = e^{-\left(k^2 + l^2\right)\frac{L^2}{4\pi^2}},$$
(1)

where k and l are zonal and meridional wavenumbers, respectively, and L is the cutoff parameter. Finally, the inverse FFT algorithm is applied to the product.

The exponential function in Eq. (1) is, up to a scaling factor, a Gaussian function with the variance $\sigma^2 = 2\pi^2/L^2$. As 95 % of the filtered waves will have wavenumber smaller than $2\sigma = 2\pi\sqrt{2}/L$, the wavelengths $\tilde{\lambda}$ that are filtered out fulfil

$$\tilde{\lambda} < \frac{L}{\sqrt{2}}.$$
(2)

After choosing an appropriate value to the parameter *L*, the perturbations with the wavelengths $\tilde{\lambda}$ that are removed by the application of the low-pass response function in Eq. (1) are commonly assumed to consist exclusively of GWs. The complete procedure with subtraction of the filtered field from the initial one is equivalent to the filtering with the response function

$$\hat{r}_{hp}(k,l) = 1 - e^{-\left(k^2 + l^2\right)\frac{L^2}{4\pi^2}},$$
(3)

instead of Eq. (1). Therefore, we are effectively applying a high-pass filter method, and, as GWs, we consider the waves with wavelengths shorter than $L/\sqrt{2}$.

¹²⁰ The periodization procedures applied before the FFT step will be discussed in Section 2c.

121 b. Horizontal Energy Spectrum

As the width of the spectrum of GWs on a local domain is variable (see Section 4c), we aim to modify the high-pass filter method introduced above, so that the cutoff parameter reflects the actual range of GW modes. To this end, we study the specific horizontal kinetic energy spectrum, which is computed at a given altitude as a sum of energies for individual horizontal modes

$$E_{k,l}^{z} = \frac{1}{2N^{2}} \left(\hat{u}_{k,l} \hat{u}_{k,l}^{*} + \hat{v}_{k,l} \hat{v}_{k,l}^{*} \right), \tag{4}$$

¹²⁷ where $\hat{u}_{k,l}$ and $\hat{v}_{k,l}$ are horizontal Fourier transforms of zonal and meridional velocities and *N* is ¹²⁸ number of points in both horizontal directions.

¹²⁹ Making explicit the divergent and vortical properties of the flow, the previous formula can be ¹³⁰ alternatively written in the form

$$E_{k,l}^{z} = \frac{1}{2N^{2}} \frac{\hat{\zeta}_{k,l}^{z} (\hat{\zeta}_{k,l}^{z})^{*} + \hat{\delta}_{k,l}^{z} (\hat{\delta}_{k,l}^{z})^{*}}{\left(\frac{2\pi}{N\Delta x}\right)^{2} \left(k^{2} + l^{2}\right)},$$
(5)

where $\hat{\zeta}_{k,l}^z$ and $\hat{\delta}_{k,l}^z$ are horizontal Fourier transforms of horizontal vorticity and divergence. The first summand in the expression can be viewed as the rotational part of the spectrum and the second one as the divergent part.

The 2D spectrum described by Eq. (4) or (5) can be summed up to obtain a 1D spectrum. The exact procedure of the spectrum computation and the derivation of the second formula is described in detail in Appendix A. ¹³⁷ By the theory, we can expect the horizontal kinetic energy spectrum being proportional to $K^{-5/3}$ ¹³⁸ for GW-dominated mesoscale (Menchaca and Durran 2019) and proportional to K^{-3} for larger ¹³⁹ scales (Geller and Gong 2010; Vallis 2017; Gage and Nastrom 1986). The latter dependence, ¹⁴⁰ based on the quasi two-dimensional theory of turbulence at large scales, is related to the enstrophy. ¹⁴¹ Such theoretical proportionalities were repeatedly confirmed by observational studies (Nastrom and ¹⁴² Gage 1985; Lindborg 1999) and from high-resolution simulations (Blažica et al. 2013; Skamarock ¹⁴³ 2004).

144 c. Periodization Method

For computation of the horizontal energy spectrum, we used discrete Fourier transform (DFT). However, DFT assumes that the data are periodic, which is not true for a local domain. Removal of these aperiodicities is essential to get a correct, unbiased spectrum (Bierdel et al. 2012).

There are different approaches to this problem. The method we implemented for the spectrum computation is a detrending method presented by Errico (1985). It is based on subtracting the linear trend from each row and column of the data, where the slope is computed using the boundary values only. If the data values are denoted by $b_{i,j}$, i = 1, ..., N, j = 1, ..., M, we can write the slope of a line connecting the first and the last element in *j*-th column as

$$s_j = \frac{b_{N,j} - b_{1,j}}{N - 1}.$$
 (6)

The values along the line are then modified by a line with the slope s_j so that the resulting column is periodic,

$$b_{i,j}' = b_{i,j} - is_j + \frac{1}{2} \frac{N+1}{N-1} \left(b_{N,j} - b_{1,j} \right).$$
⁽⁷⁾

¹⁵⁵ The same procedure is applied also on rows.

The drawback of this method is that it creates artificial small-scale structures (Denis et al. 2002). Hence, we only apply the method to obtain the horizontal kinetic energy spectrum and derived spectral characteristics. We do not use it for the high-pass filtering with a fixed cutoff parameter. In this case, we only subtract global linear trend in the data (evaluated by fitting a plane to the data). The boundary effects are assumed to be small (Kruse and Smith 2015), but we note that especially for larger cutoff values, the effect of non-periodicity can extend further in the domain and project to our drag estimates. This effect can be mitigated by a replacement of DFT by discrete cosine transform (Denis et al. 2002). In our case the application of the discrete cosine transform resulted in negligible differences (see Fig. S1 in the Supplementary Material) with the DFT based results, confirming that the boundary effects are small in our study. For consistency with Kruse et al. (2022) we base our method on DFT.

¹⁶⁷ *d. Methods for Dynamical Cutoff Selection*

Following the changepoint analysis of Burgess et al. (2013), we propose two modifications of the Gaussian high-pass filter method, in which we use horizontal kinetic energy spectra to estimate an optimal cutoff value variable with time and altitude. To get an integral information on GWs from the spectra, the spectra are smoothed by moving average with the length of 15 hours before applying any of the statistics described below.

173 1) Spectral Slope Method

The first modification of the high-pass filter method evaluates the cutoff parameter from the slopes in the energy spectrum.

Based on the characteristic slopes, we can identify three parts of the spectrum - synoptic, mesoscale and for the shortest wavelengths, starting from the so-called effective resolution, we observe a steep descent of the kinetic energy. The exact value of the effective resolution of a model depends on a set of factors (horizontal and vertical resolution, numerical dissipation, filtering, etc.). Below this threshold specific GW modes can still be partially resolved, but as we go to smaller wavelengths, an increasing part of the modes are unresolved.

¹⁸² By assuming that GWs dominate the mesoscale part of the spectrum in our domain, we choose the ¹⁸³ cutoff using the wavelength at which the spectrum slope changes from -5/3 (the exact connection ¹⁸⁴ of the wavelength to the cutoff value is through the Eq. (2)).

The detection of the change-of-slope wavelength involves some non-trivial technical aspects: The algorithm subdivides the range of wavelengths in the logarithmic spectrum plot into two sequences, the first sequence well fitted by a line with an arbitrary slope and the second sequence well fitted by a line with the slope -5/3. The second sequence is then considered the range of GWs. The algorithm constructs the sequences iteratively in a greedy manner, always adding the ¹⁹⁰ neighboring wavelength into the sequence into which its neighboring wavelength fits better. The ¹⁹¹ error metric used for comparing the quality of the sequences is their line fitting error. The sequences ¹⁹² are initialized by the wavelength corresponding to the effective resolution, which is assumed to ¹⁹³ lie in the GW range, and by the longest wavelength present, respectively, which is assumed to lie ¹⁹⁴ outside the GW range. The full algorithm is described in pseudocode in Appendix C.

This process described above is applied on each of the smoothed spectra, resulting in a cutoff length for each time step (apart from the initial and final time steps that are discarded during the smoothing).

¹⁹⁸ Further on, we will refer to the high-pass filter method that uses cutoff specified by this algorithm ¹⁹⁹ as the spectral slope method.

200 2) Divergence Dominated Method

According to Saujani and Shepherd (2006), a simple way to distinguish between balanced and 201 unbalanced flow exists by comparing the relative magnitudes of divergent and rotational flow. For 202 balanced dynamics, the divergent part is much weaker than the rotational motion and vice-versa. 203 This motivates us to determine the cut-off based on the intersection of divergent and rotational 204 spectra following Burgess et al. (2013), assuming that GWs (although partly also having the 205 rotational component) dominate the spectrum, where the divergent part dominates. Detection of 206 the wavelength at which the divergent spectrum equals the rotational is not straightforward, as 207 there can be multiple intersections of the spectra. The applied algorithm therefore considers also 208 distances between individual intersections and chooses a maximal wavelength of a divergence-209 dominated interval such that there is no divergence-dominated wavelength interval for larger 210 wavelengths that would be longer than the vorticity-dominated interval for smaller wavelengths. 211

To the high-pass filter method using cutoff specified at each time step (again apart from the initial and final time steps because of spectrum smoothing) by this algorithm, we will refer as the divergence dominated method.

e. S3D Method

For comparison, we also derive GWD estimates using the widely used S3D method for GW detection (Lehmann et al. 2012; Stephan et al. 2019; Preusse et al. 2014; Ern et al. 2017; Krisch et al. 2017; Strube et al. 2021; Krasauskas et al. 2022).

In the applied settings, temperature data are analyzed. Separation into background and GWs is 219 performed by a FFT high-pass filter retaining all spectral components corresponding to wavelengths 220 shorter than 500 km. The whole volume is then divided into overlapping cuboids of 100 km x 221 100 km x 11 km (zonal x meridional x vertical direction) with cuboid centres every 0.39° in zonal 222 and meridional direction and every 1 km in vertical direction. In the cuboids sinusoidal fits of 223 the most and second significant wave component are performed resulting in the 3D wave vector, 224 amplitude and phase for both wave components (Lehmann et al. 2012). Fit results where the 225 wavelengths exceed 3 times the vertical or 3.5 times the horizontal cuboid size are suppressed 226 in the fitting by adding a penalty to the χ^2 -values used in the fitting and, where still present, 227 removed afterwards. According to Ern et al. (2004) GW momentum flux is then determined from 228 the wave parameters. 229

3. Data and Implementation

We use data from a hindcast simulation of Weather Research and Forecasting (WRF) Model (Skamarock et al. 2019b) on a local domain covering parts of Southern America, Antarctica and the south-east of the Atlantic Ocean described in Kruse et al. (2022). The GW filtering is applied on the full simulation domain displayed in Fig. 1, described using the simplified Lambert Conformal map projection. Following Kruse et al. (2022), we subsequently divide the domain into three GW hotspots, see Fig. 1, Southern Andes (SA), Antarctic Peninsula (AP) and South Georgia (SG), where we estimate the mountain wave drag (MWD).

After the initialization at 12 UTC on 8th October 2010, the model was integrated for 11 days with the output frequency of 15 minutes. The simulation was guided by 6-hourly operational IFS analyses via initial and boundary conditions. The model uses hybrid sigma-pressure vertical coordinate, but for the computations, the data (pressure, potential temperature and velocity components fields) were first linearly interpolated on equidistant vertical levels of geopotential height with 1 km spacing. To make the computation of horizontal derivatives easier, after the filtering, we interpolate the data

FIG. 1. Horizontal domain with marked subdomains Southern Andes (SA), Antarctic Peninsula (AP) and South Georgia (SG).

²⁴⁶ also horizontally from the simplified Lambert Conformal map projection of the model to a regular
²⁴⁷ grid defined by values of latitude and longitude with the same horizontal resolution as the original
²⁴⁸ data (the average distance between points along parallels and meridians is set to be 3 km). This
²⁴⁹ regridding is performed using the ESMF_regridding package in NCAR Command Language (NCL
²⁵⁰ 2019).

The scripts and algorithms were implemented partly in Python and partly in NCL. They were parallelized using the Python multiprocessing package and the program GNU parallel (Tange et al. 2011). The diagnostic algorithms are accessible through the link in Procházková (2021).

254 Gravity Wave Drag

As the wind blows against a mountainside, it excites mountain waves (MWs), and it exerts 255 the pressure force on the mountain surface. In accordance with the Newton's third law, this 256 gives rise to a drag force acting in the opposite direction on the air, which is called mountain 257 drag. The mountain drag is deposited not only locally in the vicinity of the mountain, but is also 258 propagated by the MWs in a form of MFs to the free atmosphere, where the mountain wave drag 259 (MWD, a subset of GWD) is deposited at the level of their dissipation (Kruse and Smith 2018), 260 i.e. resulting in MF divergence. Estimating the drag exerted by GWs higher up from the surface 261 is a complex task for which various approximations exist. Here we follow the method used by 262 Kruse et al. (2022) and Kruse and Smith (2015) based on spatial averaging across the MW source 263

regions. The hotspot regions follow Kruse et al. (2022) and have been defined to contain as much 264 of the wave activity from individual sources as possible, while while minimizing the influence 265 of lateral propagation of large-scale waves through the subdomains. The assumption on the area 266 of the subdomains is that $\overline{u'} = 0$, where $\overline{(\cdot)}$ is an average over a 2D domain A and u' denotes wave 267 perturbation, while the synoptic scale variables do not vary considerably over the subdomains. 268 Obviously, the choice of the area A can never be optimal, which can introduce another portion 269 of uncertainty. Its quantification is however out of the scope of the current manuscript and we 270 follow the choice of the subdomains from Kruse and Smith (2015) (the horizontal dimensions 27 of the subdomains are approximately 1700 x 1700 km² for SA, 1800 x 1400 km² for AP and 700 272 x 900 km^2 for SG, Fig. 1). 273

The resulting MFs form a rank-two tensor, whose divergence represents the MWD vector. In spherical coordinates, defined by the radial coordinate r, latitude φ and longitude λ , MWD components are computed as (taking into account the shallow atmosphere approximation implicit to the WRF model to substitute the radius r by the radius of Earth r_e):

$$MWD_x = MWD_{xx} + MWD_{yx} + MWD_{zx},$$
(8a)

$$MWD_{xx} \approx -\frac{r_e}{A} \left[\int u'^2 \,\mathrm{d}\varphi \right]_{\lambda_1}^{\lambda_2},\tag{8b}$$

$$MWD_{yx} \approx -\frac{r_e}{A} \left[\int u'v' \cos\varphi \, d\lambda \right]_{\varphi_1}^{\varphi_2} - \frac{r_e}{A} \iint u'v' \sin\varphi \, d\lambda \, d\varphi, \tag{8c}$$

$$MWD_{zx} \approx -\frac{r_e^2}{A} \frac{1}{\hat{\rho}} \partial_r \iint \hat{\rho} u' w' \cos \varphi \, d\lambda \, d\varphi, \tag{8d}$$

$$MWD_{y} = MWD_{xy} + MWD_{yy} + MWD_{zy},$$
(8e)

$$MWD_{xy} \approx -\frac{r_e}{A} \left[\int u'v' \,\mathrm{d}\varphi \right]_{\lambda_1}^{\lambda_2},\tag{8f}$$

$$MWD_{yy} \approx -\frac{r_e}{A} \left[\int v'^2 \cos \varphi \, d\lambda \right]_{\varphi_1}^{\varphi_2} - \frac{r_e}{A} \iint v'^2 \sin \varphi \, d\lambda \, d\varphi, \tag{8g}$$

$$MWD_{zy} \approx -\frac{r_e^2}{A} \frac{1}{\hat{\rho}} \partial_r \iint \hat{\rho} v' w' \cos \varphi \, d\lambda \, d\varphi, \tag{8h}$$

where the dashed quantities u', v' and w' are the perturbation components of flow velocity and $\hat{\rho}$ is the area average of the density. The area A bounded by latitudes φ_1 and φ_2 and longitudes λ_1 and λ_2 is given by

$$A = \iint r^2 \cos \varphi \, d\lambda \, d\varphi \approx r_e^2 \left(\lambda_2 - \lambda_1\right) \left(\sin \varphi_1 - \sin \varphi_2\right). \tag{9}$$

The complete derivation of analogous formula for Cartesian coordinates is shown in Appendix B. The additional terms that appear in the equations for the spherical coordinates (compared to the equations in Cartesian coordinates) result from the differentiation of geometric factors such as $\sin \varphi$.

For the S3D method, only the vertical drag components are evaluated from temperature amplitudes using the approach described e.g. in Ern et al. (2017).

287 4. Results

288 a. Broad Spectrum of GWs

First, we show the mean spectrum of horizontal kinetic energy for the altitude of 20 km in Fig. 2, 289 evaluated for the whole WRF domain. To guide the reader's eye, the theoretical slopes of -5/3, 290 where we expect GWs to dominate the wave field, and -3 are illustrated by dashed curves below 291 the spectral line. The spectrum follows approximately the -5/3 slope for horizontal wavelengths 292 from approximately 25 km up to about 800 km in an average over the simulation period. By eye, 293 the hypothetical upper bound for the GW dominated spectrum given by the spectral slope approach 294 is larger than the wavelength of approximately 354 km, corresponding to the cutoff length 500 km 295 (denoted in Fig. 2 by vertical line), used in the high-pass filter method by Kruse et al. (2022). The 296 range up to which the spectrum follows the slope -5/3 is dependent on the altitude, which will 297 be studied in more detail in Section 4c. For example, at the altitude of 40 km, the upper bound 298 of the GW dominated spectrum is higher than 1000 km in average (plot of the mean spectrum 299 of horizontal kinetic energy for 40 km is shown in the Supplementary Material in Fig. S2). 300

The spectrum with its shape also varies in time. To illustrate this, we show the time evolution of a local spectral slope between neighbouring wave modes for the altitude of 20 km in Fig. 3 (a similar plot for 40 km is in the Supplementary Material in Fig. S4). The presented local slopes in the figure, evaluated from adjacent data values, were calculated from immediate specific horizontal energy spectra after a noise reduction by the 15-point Savitzky–Golay filter (Ostertagova

FIG. 2. Horizontal spectrum of specific horizontal kinetic energy at 20 km. Plot displays the median spectrum over the time period, the filled region denotes the range between the lower and upper quartile. Vertical line denotes the wavelength of about 354 km that corresponds to the cutoff 500 km. The dotted lines display the theoretical slopes -3 and -5/3.

and Ostertag 2016). With a suitably chosen colour scale, we can see that the GW dominated part 310 of the spectrum can be well distinguished during the whole simulation. The lower bound corre-311 sponding to the effective resolution is especially sharp and stable. However, the exact identification 312 of the upper bound is more tricky (the developed algorithm is described in Subsection 4c), because 313 at this region, the spectrum is often dominated by isolated peaks that are identifiable by zero slopes 314 (yellow colour). Those peaks are often missed by the algorithm and also it cannot be said with 315 certainty that those peaks belong to GW modes. This brings an inevitable uncertainty, however 316 small, to our MF and MWD estimates presented in Subsections 4c and 4d. 317

Next, we show in Fig. 4 the rotational and divergent components corresponding to spectrum of horizontal kinetic energy at the altitude of 20 km (Fig. S2 in Supplementary material for 40 km). As discussed in Section 2c, we can see the domination of the divergence component in the mesoscale part of the spectrum and the prevalence of the rotational component for longer wavelengths. Again, note that the median cut-off wavelength determined by the divergence dominated method is much larger than the wavelength corresponding to the 500 km cut-off, which is denoted by the grey vertical line in the figure.

FIG. 3. Approximation of local slopes in the horizontal spectrum of specific horizontal kinetic energy at 20 km (colours). The black lines visualise the time evolution of the effective resolution and of the upper bound for GWs (described in Section 2d).

FIG. 4. Decomposition of horizontal spectrum of specific horizontal kinetic energy at 20 km into divergent and rotational part. Plot displays the median rotational and divergent part of the spectrum over the time period. Vertical line denotes the wavelength of about 354 km that corresponds to the cutoff 500 km.

³³¹ b. Sensitivity of the MWD Estimates to the Cutoff

Further motivation for a modification of the traditional high-pass filter method used for GW separation is its sensitivity to the choice of the cutoff length, which is demonstrated in Fig. 5 for the altitude of 20 km (for 40 km, it is shown in the Supplementary Material in Fig. S5). To obtain these figures, we computed multiple MWD estimates following Section 3 from the high-pass filtered data with constant cutoff, but for multiple cutoff choices ranging between 250 km and 1550 km with a step size of 50 km. From the set of multiple MWD estimates for each time and domain, the derivative with respect to the cutoff length was computed using finite differences. For an easier interpretation of significance of the sensitivity, the derivatives are scaled by the median of the absolute value of the MWD component over the time and cutoff length, i.e. the sensitivity is plotted as:

$$\frac{1}{\left(med_{t,L}\left(|MWD|\right)\right)(z)}\frac{\mathrm{d}MWD\left(t,L,z\right)}{\mathrm{d}L}.$$
(10)

The high-pass filter method relies on the existence of a clear separation of the mesoscale modes 342 from synoptic scale modes, i.e. the existence of a spectral band where the MWD and MF estimates 343 do not significantly depend on the cutoff length is assumed. In Figure 5, we show the time evolution 344 of the dependence of the zonal and meridional component of the MWD on the cutoff length at the 345 altitude of 20 km for the three subdomains. Blue colours indicate that the drag decreases with 346 cutoff, whereas red colours mean that it increases. Immediately we see that the desired band, where 347 the MWD sensitivity to the cutoff length is near zero (indicated by white colour in the plots) is 348 very narrow during some events and its location varies sharply over time. 349

For the zonal MWD component, the constant cutoff of 500 km indeed falls into the low sensitivity region for the SA and AP subdomains producing unbiased MWD estimates during some periods of the simulation. However, at other instants the white band is very narrow and fluctuating over a large range of wavelengths (from around 400 km to more than 1000 km).

As for the SG subdomain, the sensitivity here is generally stronger (in relative terms) than for AP and SA and the white band is even more variable over time, which might be related to the fact that the SG subdomain is the smallest one, as discussed in Section 5. Note that for SG in the first days of the analyzed period the sensitivity of the zonal MWD component shows red regions embedded between blue regions around the 800 km cutoff, meaning that the drag is increasing when allowing for both longer and shorter wavelengths besides the red region.

For the meridional MWD component, the estimates show sensitivity similar to the sensitivity of the zonal component. Only for the AP domain, the sensitivity is relatively weak and the constant cutoff of 500 km is an almost ideal choice except for some intermittent events. However, these findings hold only for the studied period and can change especially with a different background wind field and its orientation with respect to the topography. The sensitivity of MWD estimates to the cutoff is further dependent on the altitude in question. In the Supplementary Material, we show the sensitivity of MWD components at 40 km. Generally speaking, for the upper stratospheric altitudes the sensitivity is smaller (presumably due to the dominant importance of vertically propagating GWs, as will be discussed further in the text). At tropospheric levels, the sensitivity is far stronger, but the hypothesis of the existence of the GW dominated part of the specific horizontal kinetic energy spectrum is increasingly invalid.

Altogether, the results suggest that the MWD estimates from the high-pass filter method may contain significant uncertainty due to the sensitivity on the cutoff value and it is generally not possible to choose a constant value of the parameter. For this reason, we propose two modifications to the method that sets the cutoff value in every time step using the information from the energy spectrum analysis.

381 c. Comparison of the Methods

The analysis of the total specific horizontal kinetic energy spectrum (averaged over 15 hours to eliminate local noise effects emerging from incomplete wave periods) provided two important natural bounds on the simulated GW spectrum. The first bound is the effective resolution, which is a limiting wavelength for the fully resolved waves by the model (the black bottom line in Fig. 3; Klaver et al. 2020). This bound is estimated as the wavelength at which the values in the horizontal spectrum of specific horizontal kinetic energy deviate significantly from a straight line fitted to the mesoscale part of the spectrum.

Fig. 6 shows that the vertical profile of effective resolution follows the variations of vertical resolution with height suggesting that vertical resolution of the model can be an important factor in our simulation, controlling the effective horizontal resolution. The connection of vertical resolution and the horizontal scale of resolved processes was studied e.g. in Skamarock et al. (2019a).

The effective resolution is evaluated from the spectrum for the entire domain and it does not necessarily mean that there are no waves with horizontal wavelengths shorter than this threshold. Locally, GW modes can be present with horizontal wavelengths smaller than the effective resolution that are resolved by the model due to the sufficiently long vertical wavelengths. By applying a lowpass filter to cut the shorter modes off, we would lose a part of the GW related information. Hence,

FIG. 5. Derivative of MWD components with respect to the cutoff for different subdomains: a) MWD_x , SA, b) MWD_y , SA, c) MWD_x , SG, d) MWD_y , SG, e) MWD_x , AP, f) MWD_y , AP. The colours code the relative MWD change with respect to the median of the absolute value of MWD computed over time and cutoff length. The two colours close to white represent the change of the MWD component smaller than 10% of the median if the cutoff length is increased by 100 km.

for means of the GW separation the removal of the wavelengths shorter than the effective resolution
is not beneficial. This is confirmed by visual comparison of the filtered fields with and without
the application of a low-pass filter (Fig. 7).

The second bound, which can be derived from the total kinetic energy spectrum is the longest wavelength, until which the spectrum of horizontal kinetic energy follows the theoretical shape

FIG. 6. Average vertical profile of effective resolution (blue line) with its variation (blue area) throughout the simulation. The red line depicts the average distance between two neighbouring vertical model levels.

FIG. 7. Comparison of high-pass filter and a combination of high-pass and low pass filter. a) Perturbation field of the pressure obtained by high-pass filter method with the cutoff length computed from the slopes in the horizontal kinetic energy spectrum. b) Perturbation field of the pressure obtained by combination of highpass filter and low-pass filter with the cutoff length for the low-pass filter set on the basis of the effective resolution.

for the mesoscale spectrum (presumably GW dominated; upper black line in Fig. 3) introduced in the spectral slope method presented in Section 2c. An alternative natural bound is the intersection of divergent and rotational part from the spectrum decomposition introduced in the second part

FIG. 8. GW range and effective resolution at 20 km. Example of spectra from nine randomly chosen time instants. The black vertical line denotes the effective resolution, the orange vertical line denotes the upper bound of the horizontal wavelengths with dominant GW.

of Section 2c. We argue that choosing a cutoff based on the spectral information is a physically
optimal approach, although it turns out that determination of this bound brings along a decent level
of uncertainty in both the spectral slope method and the divergence dominated method.

The reason why determining the upper bound on the GW part of the spectrum from the slopes 416 is complicated can be seen e.g. for the altitude of 20 km in Fig. 8 (or for the altitude of 40 km 417 in Fig. S6 in the Supplementary Material). The problem is that the horizontal kinetic energy 418 spectra are not smooth in the range of wavelengths for which the bound is sought, but, near the 419 upper bound, are dominated by individual modes. Therefore, an application of a simple algorithm 420 based on fitting a line to a part of the GW dominated spectrum, which would terminate on the 421 first random departure, could result in too small cutoff values. As we cannot a priori rule out 422 the possibility that the dominant modes in this uncertain region are connected to GWs (e.g. inertia-423 GWs sourced by the orography in the domain; see Section 5), we have to apply a more advanced 424 greedy algorithm, as described in Section 2d. 425

The mean vertical profiles and variability of the dynamically estimated cutoff for the analysed simulation using both methods are shown in Fig. 9. As for the spectral slope method (Fig. 9a), the mean cutoff is largest approximately between 20 km and 40 km, where it exceeds 1000 km. The cutoff gets gradually smaller both above in the upper stratosphere and mesosphere and below in the lower stratosphere. The mean cutoff is smaller than 500 km only above 60 km and below

10 km. This is reflecting the mean zonal wind profile (see Fig. 14 in Kruse et al. (2022)) with 434 a tentative explanation that the maximal wavelength of vertically propagating GWs is decreasing 435 with the decreasing background winds in the upper stratosphere, numerical damping as cause for 436 this effect can be excluded in this WRF configuration. In this lower to middle tropospheric region, 437 it is generally not expected that GWs will dominate any part of the horizontal kinetic energy 438 spectrum and we do not produce MWD estimates in this region. The time variability of the cutoff 439 value at all levels in the stratosphere is large and the standard deviation is of a similar magnitude 440 as the mean cutoff. 441

The vertical profile of the cutoff value obtained by the divergence dominated method is shown 442 in Fig. 9b. Similarly to the spectral slope method, the cutoff values are continuously rising from 443 the troposphere. Above the altitude of approximately 15 km, the mean cutoff value remains about 444 approximately 1000 km, with less pronounced altitude variability than in the spectral slope method. 445 On the other hand, the shaded area in the plot still show high temporal variability. Within the range 446 given by the standard deviation, the cutoff values obtained by this method vary mostly between 447 750 and 1250 km. The agreement between the two methods further supports the choice of a GW 448 separation method with a time varying cutoff. 440

⁴⁵⁰ A significant difference between the cutoff profiles in Fig. 9 is the decrease of cutoff above the ⁴⁵¹ altitude of 60 – 65 km for the spectral slope method, that is not present in the plot for divergence ⁴⁵² dominated method. The reason is that the shape of the kinetic energy spectra at these altitudes ⁴⁵³ changes so that there is no clear separation into parts with different slopes and the spectral slope ⁴⁵⁴ method is therefore unreliable at the higher levels.

Next, MWD estimates from the dynamical cutoff methods are compared with the original high-457 pass filter method for a constant value of the cutoff length 500 km, which is used in Kruse et al. 458 (2022), and also with the S3D method. In Fig. 10, the zonal and meridional MWD estimates 459 from the two methods with variable cutoff and a method with a constant cutoff are compared 460 at 20 km for each hotspot (Fig. S7 in the Supplementary Material depicts the estimates at 40 km). 461 As suggested by the sensitivity analysis in Fig. 5 and the large variability of the dynamical cutoff 462 estimates in time, the difference between the methods depends on time and also on the hotspot 463 region (and altitude). For AP, the episodes of larger differences between the MWD estimates are 464

FIG. 9. Mean vertical profile of the cutoff parameter. The filled region depicts the standard deviation corresponding to the temporal variability. a) Spectral slopes method. b) Divergence dominated method.

⁴⁶⁵ rather sporadic. For SA and SG the differences have larger magnitude and are more frequent.

⁴⁶⁶ For the meridional MWD component the differences are smaller.

FIG. 10. Comparison of the improved method and high-pass filter method with constant cutoff at 20 km: a) MWD_x , SA, b) MWD_y , SA, c) MWD_x , SG, d) MWD_y , SG, e) MWD_x , AP, f) MWD_y , AP. The orange and green lines visualize the time evolution of MWD computed using the wave perturbation from the methods with dynamically changing cutoff. The blue lines describe the evolution of MWD using the high-pass filter method with constant cutoff length 500 km. The filled blue regions represent the possible values of MWD in individual times for the cutoff range 250 – 1550 km.

Regarding the S3D method, vertical momentum fluxes that are derived from the S3D temperature 473 perturbation are well correlated with the momentum fluxes obtained from perturbation separated 474 by the methods with Gaussian filter, even though the values are lower. This is easily understandable 475 as the wavelengths from S3D method in our configuration cannot be larger than 500 km and the 476 contribution from long waves is therefore missing. However, S3D method encounters difficulties 477 when evaluating the resulting drag, because the method is not continuous (different sines can be 478 fitted in adjacent levels) and therefore the vertical derivative of momentum fluxes creates noise at 479 some timesteps. Up to these noise perturbations, the time evolution of the vertical drag from the 480 S3D method is similar to the other methods (not shown), but its magnitude is generally significantly 48 lower. 482

Statistical differences between the four methods at the altitude of 20 km are summarised in Table 1. Given the fact that the results derived from the S3D method contain a few nonphysical outliers and that the distributions of MWD are slightly distinct from the normal distribution (especially in the fact that they are showing much longer tails), we used the median and interquartile range (IQR) instead of the mean and the variance for the comparison in order to obtain more robust statistical description.

The median drag component values range from -0.39 to 0.00 for the high-pass filter methodologies 489 and from -0.08 to 0.06 for the S3D method, with the IQR larger than the median, signifying high 490 variability and intermittency seen already in Fig. 10. Comparing the individual methods, we 491 can generally see that the median and IQR differences between the methods are smaller between 492 the dynamical cutoff methods than between each of them and the constant cut-off method. The 493 pronounced differences between IQRs of MWD components (being generally smaller for the 494 method with constant cutoff than for the spectral based) mean that for individual events the 495 difference of actual drag estimates can be more than 100 % larger than the median difference 496 suggests. 497

Similar statistics are shown in Table 2 for the altitude of 40 km. Here the median MWD estimates
for all methods and regions are larger than and hence IQR smaller than at 20 km in relative terms.
The difference in median MWD values between the methods is around 10 % of the MWD median
value and similarly for the IQR is estimates. The drag estimated by the constant cutoff methodology

is generally smaller than for the two variable cutoff methods for all regions and components, but
 its vertical component is still much stronger than from the S3D method.

A notable aspect of the results for both altitudes is that the differences between high-pass filter methods in median MWD_{xx} and MWD_{yx} estimates are of comparable magnitude with the differences in MWD_{zx} despite the median MWD_{zx} drag being stronger by an order of magnitude. This means that the relative uncertainty in these MWD components connected with horizontal flux divergences is much bigger.

To sum up, there are large differences between MWD estimates from S3D and high-pas filter methods and although the assumption of a constant cutoff does not result in pronounced systematic biases of the zonal MWD or its components, the estimates from the dynamic methods can lead at individual events to differences larger than the order of magnitude of the median MWD values.

⁵¹⁷ When we focus on individual events at 20 km, one of the most pronounced differences between ⁵¹⁸ the methods can be seen on 12^{th} October for the zonal MWD component in SA (Fig. 10a). ⁵¹⁹ The *MWD_x* estimate from the constant cutoff method was small but negative, whereas the spectral ⁵²⁰ slope method (and with small time-shift also the divergent dominated method) estimated strong ⁵²¹ acceleration up to 2 m s⁻¹day⁻¹. This event is reflected also in differences of the meridional MWD ⁵²² in SA (Fig. 10b), even though the magnitude of the difference is not as pronounced as for the zonal ⁵²³ component.

TABLE 2. Medians and interquartile ranges (IQR) for zonal MWD and its components using different methods at the altitude 40 km. Values are given in m s⁻¹day⁻¹.

For the SG subdomain (Figures 10c and 10d), a similar pronounced difference occurs slightly 524 later, around 12th October, 20:00. A tentative hypothesis mentioned already in the previous section, 525 is the horizontal propagation of waves with wavelengths larger than the wavelengths corresponding 526 to the chosen constant cutoff value (probably downstream propagating inertia-GWs), which would 527 not be captured by the method with constant cutoff in both subdomains. The fact that in the 528 divergence dominated method the values are also not so high in this time period supports this 529 hypothesis, as this method might also be able to capture inertia-GWs only to some extent because 530 of their contribution to the rotational component. For the AP subdomain around 12th October, there 531 are also visible differences between the estimates of both MWD_x and MWD_y , although smaller than 532 for the other two subdomains due to the smaller sensitivity of the MWD around this date in AP. 533

⁵³⁴ *d. Impact of GWs with Larger Horizontal Wavelengths*

In this subsection, we study the sensitivity of individual parts contributing to the zonal MWD component, i.e. the zonal divergence of a zonal flux of zonal momentum (MWD_{xx}), meridional divergence of a meridional flux of zonal momentum (MWD_{yx}) and vertical divergence of a vertical flux of zonal momentum (MWD_{zx}).

The sensitivity of those contributions for each hotspot is shown in Fig. 11. Generally, for all subdomains, the dependence is much stronger for the parts with horizontal divergence MWD_{xx} and

 MWD_{yx} than for MWD_{zx} . Because the sensitivity expresses the fact that the choice of the cutoff 541 length determines the accepted portion of GW modes, this means that the horizontal flux com-542 ponents are more exclusively connected with GW modes with longer horizontal wavelengths than 543 the vertical flux components, as expected from linear theory and observed by aircraft (Smith and 544 Kruse 2017) - the horizontal wave momentum flux components compared to the vertical fluxes are 545 more exclusively connected with GW modes with longer horizontal wavelengths that are increas-546 ingly affected by rotation (Teixeira 2014). Another important aspect is that the sensitivity of the 547 horizontal flux contributions has often an opposite sign, which means that the large sensitivities 548 of those two components partially compensate and do not fully project to the net MWD_x . 549

The sensitivities are reflected in differences of $MWD_{xx} + MWD_{yx}$ and MWD_{zx} estimates between 550 the constant and dynamically determined cutoff methodologies (Fig. 12 for the altitude of 20 km). 551 For the component MWD_{zx} , all the compared methods produce very similar estimates, except 552 for the period around 11th and 12th October, when the determined cutoff is exceptionally large 553 (up to 2000 km for spectral slope mathod and 1500 km for divergence dominated method). 554 The differences in the horizontal components are more pronounced during the whole simulation. 555 Both the methods with the dynamically set cutoff generally lead to substantially higher magnitudes 556 of the components MWD_{xx} and MWD_{yx} . For all hotspots, we can find large differences on 12^{th} 557 October, but for each hotspot individually there are more events with pronounced differences. 558 For example, for SA and AP we can see for the horizontal components large differences between 559 the spectral slope method and the constant cutoff method between 17th and 19th October, but with 560 only small differences in MWD_{zx} . The fact that the sensitivity is, for some events, higher for 561 the horizontal components even in the absolute numbers, is noticeable from the shaded regions 562 in Fig 12. 563

The different sensitivity to the methodology of the MWD_{xx} , MWD_{yx} and the MWD_{zx} zonal drag components is confirmed and quantified by the correlations between the time series of the MWD_x component estimates using the methods with dynamically changing cutoff and the method with constant cutoff. The Pearson correlation coefficient is for MWD_{zx} for all subdomains and tested altitudes close to one (third column in Tab. 3), whereas for the components MWD_{xx} and MWD_{yx} , the values are significantly lower (first two columns in Tab. 3).

		MWD _{xx}	MWD _{yx}	MWD _{zx}
	SA	0.76	0.21	0.88
Spectral slopes	AP	0.73	0.29	0.96
	SG	0.52	0.68	0.91
Divergence dominated	SA	0.69	0.51	0.90
	AP	0.64	0.59	0.97
	SG	0.36	0.51	0.81

TABLE 3. Pearson correlation coefficient between the methods with constant and dynamically changing cutoff for the components of zonal drag MWD_x the altitude 20 km.

Regarding the sensitivity and differences between components of the meridional drag MWD_y , the results are almost identical as for the zonal MWD components with sensitivity of the horizontal divergence parts being stronger and leading to larger differences in corresponding meridional MWD components (Figs. S10 and S12 in the Supplementary Material) Also, similar results can be derived for the level of 40 km (Figs. S8 and S9 for the zonal component and Figs. S11 and S13 for the meridional component).

FIG. 11. Derivative of MWD_x components with respect to the cutoff, rescaled by the median, at the altitude of 20 km for different subdomains: a) MWD_{xx} , SA, b) MWD_{yx} , SA, c) MWD_{zx} , SA, d) MWD_{xx} , SG, e) MWD_{yx} , SG, f) MWD_{zx} , SG, g) MWD_{xx} , AP, h) MWD_{yx} , AP, i) MWD_{zx} , AP. The colours code the relative change of MWD components with respect to the median of the absolute value of MWD components computed over time and cutoff length. The two colours close to white represent the change of the MWD component smaller than 10% of the median if the cutoff length is increased by 100 km.

FIG. 12. Comparison of the improved method and high-pass filter method with constant cutoff at 20 km for horizontal and vertical part of MWD_x and different subdomains: a) $MWD_{hx}=MWD_{xx}+MWD_{yx}$, SA, b) MWD_{zx} , SA, c) MWD_{hx} , SG, d) MWD_{zx} , e) MWD_{hx} , AP, f) MWD_{zx} , AP. The orange lines visualize the time evolution of MWD components computed using the wave perturbation from the improved method. The blue lines describe the evolution of MWD components using the high-pass filter method with constant cutoff length 500 km. The filled blue regions represent the possible values of MWD components in individual times for the cutoff range 250 – 1550 km.

591 **5. Discussion and Conclusions**

⁵⁹² Due to their simplicity, high-pass filtering methods based on Fourier (Kruse and Smith 2015; ⁵⁹³ Gisinger et al. 2017) or cosine (Van Niekerk et al. 2018b) transforms are widely used in atmospheric ⁵⁹⁴ physics to identify GW perturbations in high-resolution simulation data. The uncertainty of the ⁵⁹⁵ GWD estimates connected with the a priori choice of the cutoff parameter used in the methods has ⁵⁹⁶ nevertheless not been studied to date. In the present study, we address this problem to show that it ⁵⁹⁷ is not possible to choose a universal constant cutoff parameter.

When studying the dependence of the zonal and meridional drag component MWD_x and MWD_y 598 estimates on the cutoff length, the results are notably sensitive to the choice of the cutoff for the 599 whole range of admissible cutoffs. However, when considering individual parts of the drag, 600 the studied quantities can be divided into two groups - those including vertical velocity (i.e. 601 vertical fluxes), and purely horizontal terms. The sensitivity of terms involving vertical velocity 602 is generally lower than the sensitivity of terms without it. In Kruse and Smith (2015), such kind 603 of behaviour is hypothesized to be caused by the shape of the vertical velocity spectrum. Also, 604 these results support the hypothesis that the sensitivity of the high-pass filter method is caused 605 mainly by the horizontally propagating GWs with large horizontal wavelengths, which contribute 606 strongly to the horizontal drag components, modifying the net value of the drag. 607

The sensitivity of the method on the cutoff length motivates modifying methods for a variable 608 cutoff parameter. The horizontal energy spectra were analysed to estimate the optimal cutoff value. 609 In general, the spectral analysis indicates that for the studied region and time the traditionally used 610 cutoff is too small. The cutoff is dependent also on the altitude, hence we estimate it at each 611 time step and altitude separately. This modification causes a decent slowdown of the methods but 612 on the other hand, it arguably reduces the uncertainty of the traditional high-pass filter method 613 drag estimates. Our comparisons show that in some cases the difference between MWD estimates 614 of the constant and dynamically set-up cutoff methods can be of the same order of magnitude as 615 the estimates. 616

⁶¹⁷ Compared to Kruse et al. (2022), inertia-GWs (Dunkerton 1984) and even internal Rossby-GWs
 ⁶¹⁸ (Teixeira and Grisogono 2008) sourced by the orography in the domain may be increasingly sampled
 ⁶¹⁹ as we allow for larger cut-off values. However, also these waves with larger horizontal wavelength
 ⁶²⁰ are not fully represented in the current generation numerical weather prediction and climate models

due to the coarse vertical resolution (Skamarock et al. 2019a) and hence we incorporate them to our MWD estimates.

There are several aspects that contaminate the accuracy of the modified methods as well. The most 623 pressing drawback of the methods with dynamic cutoff is the uncertainty emerging during the cutoff 624 specification. As already mentioned, the part of the horizontal kinetic energy spectrum between 625 GWs and synoptic scale motions is dominated by individual modes that cannot be easily attributed 626 as GWs/nonGWs but might be rather connected to e.g. inertia-GWs or Rossby-GWs. Also, 627 the determination of the critical point is performed in a logarithmic plot. Hence, the effect 628 of a small error of specification in the spectrum can result in relative large error in the cutoff length. 629 This has negative impact on the accuracy of the MWD estimates. However, note that for decent 630 detection algorithms the error from using a constant cutoff shall be always higher. 63

Another issue is that the proposed modified methods use larger cutoff lengths. Therefore, one 632 should pay attention to the choice of subdomains at which the quantities are evaluated. First, 633 the subdomain size should be large enough, so that the present waves can be averaged over 634 the subdomain. Otherwise, the assumptions of the technique applied for evaluation of MWDs and 635 MFs might not be satisfied and the results might be affected by the presence of wave perturbations 636 whose average over the subdomain is not zero. This can be the case for the smallest hotspot, 637 SG, during events with large cutoffs. Nevertheless, the comparison of the modified and constant 638 cutoff high-pass filter methods did not produce qualitatively different results between SG and other 639 hotspots, which are large enough not to be affected. Second, in the applied filtering procedures, 640 the use of a larger cutoff implies that artificial perturbations penetrate farther away from the domain 641 boundaries (for a detailed discussion, see Kruse and Smith (2015)). The subdomains thus need 642 to be distant enough from the outer boundary. Otherwise, the use of the cosine transform instead 643 of the Fourier transform or the application of another periodization method that does not generate 644 small-scale oscillation is advisable. 645

Although we analyzed only a regional simulation with a limited time-span, it is reasonable to expect that the cutoff sensitivity of the GW momentum flux and drag estimates is a robust feature, which will be pronounced particularly in the presence of horizontally propagating GWs. Even though this effect might cancel out climatologically, in short-term studies, this can cause large uncertainties of the GW momentum flux and drag estimates. The further improvement of the methods (especially precision of the cutoff specification) is object of further research. Alternatively, the filtering can be performed in the internal frequency domain with drag components evaluated by suitable time averaging of the equations of motion. Also, we plan to compare the MWD estimates with other methodologies that have not been used to estimate resolved GWD from simulations to date. Nevertheless, we argue that the dynamic cutoff methods proposed here based on the underlying spectral analysis presents a step forward in providing more accurate estimates of MWD from high-resolution model simulations.

APPENDIX A

675

Specific Horizontal Kinetic Energy Computation

Horizontal kinetic energy at an altitude z with a unitary density is given by

$$E^{z} = \frac{1}{2} \int \int \left(u^{2}(x, y, z) + v^{2}(x, y, z) \right) dx dy$$

$$\approx \frac{1}{2} \sum_{i=0}^{N-1} \sum_{j=0}^{N-1} \left(u^{2}_{i,j} + v^{2}_{i,j} \right) (\Delta x)^{2},$$
 (A1)

where $u_{i,j} = u(x_i, y_j)$ and $v_{i,j} = v(x_i, y_j)$ are the horizontal velocity components at individual grid points, *N* denotes number of grid point in each direction and Δx is the horizontal distance between grid points for both *x* and *y* directions. To evaluate the spectrum, it is convenient to describe the energy in the Fourier space. We use the definition of the two-dimensional discrete Fourier transform (DFT)

$$\hat{a}_{k,l} = \sum_{n=0}^{N-1} \sum_{m=0}^{N-1} a_{n,m} e^{-2\pi i \frac{nk}{N}} e^{-2\pi i \frac{ml}{N}}, \quad k,l = 0, \dots, N-1,$$
(A2)

682 with its inverse

$$a_{m,n} = \frac{1}{N^2} \sum_{k=0}^{N-1} \sum_{l=0}^{N-1} \hat{a}_{k,l} e^{2\pi i \frac{nk}{N}} e^{2\pi i \frac{ml}{N}}, \quad m,n=0,\dots,N-1.$$
(A3)

⁶⁶³ By the Parseval theorem for two-dimensional DFT given by equation (A2) (Sundararajan 2001), ⁶⁶⁴ it holds

$$\sum_{i=0}^{N-1} \sum_{j=0}^{N-1} \left(u_{i,j}^2 + v_{i,j}^2 \right) = \frac{1}{N^2} \sum_{k=0}^{N-1} \sum_{l=0}^{N-1} \left(\hat{u}_{k,l} \hat{u}_{k,l}^* + \hat{v}_{k,l} \hat{v}_{k,l}^* \right)$$
(A4)

with $\hat{u}_{k,l}$ and $\hat{v}_{k,l}$ obtained by the DFT of the velocity components. The symbol * denotes the complex conjugate. The latter expression can already be used to compute specific horizontal kinetic energy for individual wave numbers k, l = 0, ..., N - 1 as

$$E_{k,l}^{z} = \frac{1}{2N^{2}} \left(\hat{u}_{k,l} \hat{u}_{k,l}^{*} + \hat{v}_{k,l} \hat{v}_{k,l}^{*} \right).$$
(A5)

⁶⁰⁸ This equality can be also rewritten to use the horizontal Fourier transform of the horizontal ⁶⁰⁹ divergence δ and the horizontal vorticity ζ . As these quantities are defined as a sum of derivatives ⁶⁰⁰ of velocity components, their Fourier transform can be evaluated from algebraic expressions

$$\hat{\zeta}_{k,l}^{z} = \frac{2\pi \mathbf{i}}{N\Delta x} \left(k\hat{v}_{k,l} - l\hat{u}_{k,l} \right),\tag{A6}$$

691

$$\hat{\delta}_{k,l}^{z} = \frac{2\pi \mathbf{i}}{N\Delta x} \left(k\hat{u}_{k,l} + l\hat{v}_{k,l} \right). \tag{A7}$$

⁶⁹² These equations imply that

$$\hat{\zeta}_{k,l}^{z}(\hat{\zeta}_{k,l}^{z})^{*} + \hat{\delta}_{k,l}^{z}(\hat{\delta}_{k,l}^{z})^{*} = \left(\frac{2\pi}{N\Delta x}\right)^{2} \left(k^{2} + l^{2}\right) \left(\hat{u}_{k,l}\hat{u}_{k,l}^{*} + \hat{v}_{k,l}\hat{v}_{k,l}^{*}\right),\tag{A8}$$

⁶⁹³ which means, that Eq. (A5) can be replaced by equation

$$E_{k,l}^{z} = \frac{1}{2N^{2}} \frac{\hat{\zeta}_{k,l}^{z} (\hat{\zeta}_{k,l}^{z})^{*} + \hat{\delta}_{k,l}^{z} (\hat{\delta}_{k,l}^{z})^{*}}{\left(\frac{2\pi}{N\Delta x}\right)^{2} \left(k^{2} + l^{2}\right)}$$
(A9)

for k, l = 0, ..., N - 1, that can be simply decomposed into divergent and rotational part.

⁶⁹⁵ To obtain a 1D spectrum (either from Eq. (A5), or for the divergent and rotational part from ⁶⁹⁶ Eq. (A9)), we denote

$$K^{2} \equiv \left(\frac{2\pi}{N\Delta x}\right)^{2} \left(k^{2} + l^{2}\right) \tag{A10}$$

the square of the size of horizontal wave vector corresponding to the horizontal wavelength $\lambda = 2\pi/K$. As we need the spectrum with respect to the horizontal wavelength, we sum up the values $E_{k,l}^z$ of specific energy with similar values of *K* (Blažica et al. 2013; Sun et al. 2017). More precisely, we consider the sequence of horizontal wavenumbers

$$K_n = \frac{2\pi}{N\Delta x}n, \quad n = 1, 2, \dots, \left[\frac{N}{2}\right] - 1$$
 (A11)

⁷⁰¹ with the upper bound corresponding to the Nyquist frequency. We further denote

$$\Delta K = \frac{2\pi}{N\Delta x} \tag{A12}$$

the difference between two consecutive wavenumbers of this sequence. The specific horizontal
kinetic energy spectrum is then computed by Eq.

$$E^{z}(K_{n}) = \sum_{|(k,l)|\Delta K \in I_{n}} E^{z}_{k,l},$$
(A13)

where $I_n = (K_n - \Delta K/2, K_n + \Delta K/2)$ is an interval around K_n . The energy $E^z(K_n)$ is not the radial part of the 2D spectrum (in this case, the sum in the last equality would contain a factor *K*), but rather an average of the energy over wavenumbers near K_n .

707

708

APPENDIX B

Gravity Wave Drag in Cartesian Coordinates
We start by considering compressible inviscid flow on a rotating sphere. Using the standard scale-analysis argumentation (Cushman-Roisin and Beckers 2011), it is possible to write governing equation for the horizontal velocity components in the corotating coordinate system in the form

$$\partial_t u + u \partial_x u + v \partial_y u + w \partial_z u = -\frac{1}{\rho} \partial_x p + f v$$
 (B1a)

$$\partial_t v + u \partial_x v + v \partial_y v + w \partial_z v = -\frac{1}{\rho} \partial_y p - f u,$$
 (B1b)

where u, v and w are zonal, meridional and vertical wind components, p is the pressure and f is the Coriolis parameter.

We apply a linear perturbation method, assuming that the velocity components can be decomposed into a slowly varying mean flow and a small perturbation corresponding to the wave motion,

$$u = \langle u \rangle + u', \tag{B2a}$$

$$v = \langle v \rangle + v', \tag{B2b}$$

$$w = w', \tag{B2c}$$

where the mean vertical velocity component is taken zero. We further assume that the density is a function of altitude only. In computations, this is achieved by taking integral mean value of density $\hat{\rho}(z)$ over respective levels.

Next, we demonstrate the derivation for zonal momentum equation (B1a) only, the steps for the
 meridional component are analogous. With use of the continuity equation

$$\partial_t \rho + \partial_x (\rho u) + \partial_y (\rho v) + \partial_z (\rho w) = 0,$$
 (B3)

⁷²² it is possible to pass from (B1a) to the equation in the flux form

$$\partial_t(\rho u) + \partial_x(\rho u^2) + \partial_y(\rho uv) + \partial_z(\rho uw) = -\partial_x p + \rho fv.$$
(B4)

⁷²³ Substituting the decomposition (B2) and the assumption on density, we get

$$\partial_{t}(\langle u \rangle + u') + \partial_{x} \left((\langle u \rangle + u')^{2} \right) + \partial_{y} \left((\langle u \rangle + u') (\langle v \rangle + v') \right) + \frac{1}{\hat{\rho}} \partial_{z} \left(\hat{\rho} \left(\langle u \rangle + u' \right) w' \right) = -\frac{1}{\hat{\rho}} \partial_{x} p + f \left(\langle v \rangle + v' \right).$$
(B5)

At this stage, we average (B5) over area *A* of the selected horizontal domain, which will be denoted
by line over the quantities.

With the assumption that the perturbations of velocity components have zero average over the domain at every altitude and that the velocity field is such that the interchange of derivative and integral is possible, the first term is averaged to

$$\overline{\partial_t(\langle u \rangle + u')} = \partial_t \overline{\langle u \rangle}.$$
(B6)

⁷²⁹ Using the fundamental theorem of calculus, the averages of the second and the third term in (B5)
 ⁷³⁰ are

$$\overline{\partial_x \left(\left(\langle u \rangle + u' \right)^2 \right)} = \frac{1}{A} \left[\int \left(\langle u \rangle + u' \right)^2 \mathrm{d}y \right]_{x_1}^{x_2}, \tag{B7}$$

731

$$\overline{\partial_{y}\left(\left(\langle u\rangle+u'\right)\left(\langle v\rangle+v'\right)\right)} = \frac{1}{A} \left[\int \left(\langle u\rangle+u'\right)\left(\langle v\rangle+v'\right)dx\right]_{y_{1}}^{y_{2}}.$$
(B8)

⁷³² For the last integral on the left-hand side of (B5), we have

$$\frac{1}{\hat{\rho}}\overline{\partial_z\left(\hat{\rho}\left(\langle u\rangle+u'\right)w'\right)} = \frac{1}{A}\frac{1}{\hat{\rho}}\partial_z \iint \hat{\rho}\left(\langle u\rangle+u'\right)w'\,\mathrm{d}x\,\mathrm{d}y. \tag{B9}$$

If we further consider the average of $\langle \cdot \rangle (\cdot)'$ over faces to be zero, the previous three averaged terms can be thus simplified to

$$\overline{\partial_x \left((\langle u \rangle + u')^2 \right)} = \frac{1}{A} \left[\int \left(\langle u \rangle^2 + (u')^2 \right) dy \right]_{x_1}^{x_2}, \tag{B10}$$

735

$$\overline{\partial_{y}\left(\left(\langle u\rangle+u'\right)\left(\langle v\rangle+v'\right)\right)} = \frac{1}{A} \left[\int \left(\langle u\rangle\langle v\rangle+u'v'\right)dx\right]_{y_{1}}^{y_{2}},\tag{B11}$$

$$\frac{1}{\hat{\rho}}\overline{\partial_z\left(\hat{\rho}\left(\langle u\rangle + u'\right)w'\right)} = \frac{1}{A}\frac{1}{\hat{\rho}}\partial_z \iint \hat{\rho}u'w'\,\mathrm{d}x\,\mathrm{d}y. \tag{B12}$$

To deal with the right-hand size of equation (B5), we write the velocity as a sum of velocities of geostrophic and ageostrophic flow, $u = u_g + u_a$, $v = v_g + v_a$. Geostrophic flow is an idealized stationary flow described by the balance of pressure and Coriolis force, considering advective terms to be negligible. From equations (B1), we have

$$u_g = -\frac{\partial_y p}{\rho f}, \quad v_g = \frac{\partial_x p}{\rho f}.$$
 (B13)

⁷⁴⁰ Therefore, averaged right-hand side of equation (B5) can be written as

$$\overline{-\frac{1}{\hat{\rho}}\partial_x p + f\left(\langle v \rangle + v'\right)} = \overline{-fv_g + fv} = \overline{fv_a}.$$
(B14)

Altogether, the averaged equation (B5) has the form

$$\partial_t \langle u \rangle = -\frac{1}{A} \left[\int \left(\langle u \rangle^2 + (u')^2 \right) dy \right]_{x_1}^{x_2} - \frac{1}{A} \left[\int \left(\langle u \rangle \langle v \rangle + u'v' \right) dx \right]_{y_1}^{y_2} - \frac{1}{A} \frac{1}{\hat{\rho}} \partial_z \iint \hat{\rho} u'w' dx dy + \overline{fv_a}.$$
(B15)

The terms on the right-hand side can be divided into terms corresponding to the wave motion and terms corresponding to motions on larger scale. In particular, it is possible to identify three terms that add up to the zonal component of MWD,

$$MWD_{xx} = -\frac{1}{A} \left[\int (u')^2 \, \mathrm{d}y \right]_{x_1}^{x_2},$$
 (B16a)

$$MWD_{yx} = -\frac{1}{A} \left[\int u'v' \, \mathrm{d}x \right]_{y_1}^{y_2},$$
 (B16b)

$$MWD_{zx} = -\frac{1}{A}\frac{1}{\hat{\rho}}\partial_z \iint \hat{\rho}u'w'\,\mathrm{d}x\,\mathrm{d}y. \tag{B16c}$$

The quantity MWD_{xx} is zonal derivative of zonal flux of zonal wave momentum, MWD_{yx} is meridional derivative of meridional flux of zonal wave momentum and MWD_{zx} is vertical derivative of vertical flux of zonal wave momentum.

Analogously, for the meridional velocity component, it is possible to get equation

$$\partial_t \langle v \rangle = -\frac{1}{A} \left[\int \left(\langle u \rangle \langle v \rangle + u'v' \right) dy \right]_{x_1}^{x_2} -\frac{1}{A} \left[\int \left(\langle v \rangle^2 + (v')^2 \right) dx \right]_{y_1}^{y_2} -\frac{1}{A} \frac{1}{\hat{\rho}} \partial_z \iint \hat{\rho} v'w' dx dy - \overline{f u_a}.$$
(B17)

⁷⁴⁹ We get terms of the meridional component of MWD,

$$MWD_{xy} = -\frac{1}{A} \left[\int u'v' \, \mathrm{d}y \right]_{x_1}^{x_2},$$
 (B18a)

$$MWD_{yy} = -\frac{1}{A} \left[\int (v')^2 dx \right]_{y_1}^{y_2},$$
 (B18b)

$$MWD_{zy} = -\frac{1}{A}\frac{1}{\hat{\rho}}\partial_z \iint \hat{\rho}v'w'\,\mathrm{d}x\,\mathrm{d}y. \tag{B18c}$$
